ABSTRACT

This product for bute to present zirconium effect on Raman modes and structure of Barium Titanate Powders. The adjustment of raman indque modes of BaTiO₃ Doping by 15% zirconium causes significant broadening of the modes E (LO₄)/A₁(LO₃) and E(TO₃+ LO₂)/B₁ (50% higher) characteristic of quadratic phase BaTiO₃. The results obtained show that when zirconium rate increases, the lattice parameters increase along the axes (a) and (c) against the quadracité decrease and change of the lattice parameter following the axis (a) is more important than that the axis (c).

INTRODUCTION

Barium titanate (BT) is certainly the most studied ferroelectric material compounds. These dielectric properties found many technical applications in various fields of technology. Furthermore, BaTiO₃ is a chemically and mechanically very stable compound which has ferroelectric properties in a temperature range including room temperature (Megaw et al., 1947). It is relatively easy to develop and can be prepared as single crystals or ceramics. Because of its less complicated structure than that of many other ferroelectric materials; it also provides a better approach to the phenomena. These different characteristics have made him "the equivalent iron" of ferroelectric materials and so far the number of jobs that are done in the world on the influence of various parameters (especially doping) on physical properties chemical barium titanate is impressive. In particular, when replacing the B-site of the structure, it may in some cases lead to disordered dipolar compounds having advantageous physical properties

with regard to the original multiple industrial applications. In effect the structural properties of BTz_x depending on the Zr content was reported by several authors (Hennings et al., 1982, Kuang et al., 2009, Julphunthonga et al., 2013, Reddy et al., 2007). For example Hennings et al (Hennings et al., 1982) show that these crystallize in the ceramic tetragonal phase up to 25% zirconium and in the cubic phase in the range of x = 0.25 to 1 and Kuang et al (Kuang et al., 2009) That show the structure of the system is BZxT Undergoing a transformation from tetragonal (for BT) to orthorhombic (for BZ_{0.12}T) at room temperature, one hand Phongthorn l'autre et al (Julphunthonga et al., 2013) aussi indicate indication, the crystal structure of rhombohedral to BZxT Was Transformed, tetragonal and cubic phase with respectivement Increasing zirconium happy. However, the effect of the rate of the dopant on the mid-height width and the position of the Raman modes BT was not reported. In this study, the structural properties and the evolution of the Raman modes of barium titanate according to zirconium ratio was taken.

Experimental procedure

The samples BTZx were prepared using barium acetate ($\text{Ba}(\text{CH}_3\text{CO}_2)_2 \cdot 3\text{H}_2\text{O}$), zirconium acetate ($\text{Zr}(\text{CH}_3\text{CO}_2)_4 \cdot x\text{H}_2\text{O}$), and titanium alcoxide. The modification was based on the substitution of Zr^{4+} in sublattice B (Ti^{4+}). The process of the preparation of BTZx is detailed in another works (Elbasset et al., 2015). Phase identification of the samples was performed using X-ray diffraction (Cu K ray, $\lambda = 1.5418 \text{ \AA}$) and Raman spectrum.

RESULTS AND DISCUSSION

The Figure.1 shows the XRD spectra of the powders BTZx ($x = 0, 0.025, 0.05, 0.075, 0.1, 0.125$ and 0.15), calcined at 900°C for 4 hours. It shows the crystallization all of the powders in the perovskite phase with the presence of secondary microphase. Increasing the doping level causes the displacement of the peak position (220) towards lower angles (Figure 1.b), due to the fact that the ionic radii of Zr^{4+} (0.72 \AA) is higher than Ti^{4+} (0.605 \AA), therefore, the substitution of Ti^{4+} by Zr^{4+} increase the ceramic lattice parameter. To highlight the influence of zirconium on the structural state of BaTiO_3 , we calculated lattice parameters a and c of BTZx, by the use of CMPR program. The evolution of the parameters a and c as well as the c/a ratio (quadracit ) and their difference for tenure Zr studied, is shown in tableau.1 and shown in Figure 2. The results show that when the zirconium rate increases, the lattice parameters increase along the axes (a) and (c) against the quadracit  decrease. For $x < 5\%$ there is a slight variation depending on the parameter but from 7.5% there is a change in linearity (Fig .2). It is also noted that the change of the lattice parameter following the axis (a) is greater than that of the axis (c) (Fig .3). In fact the rate of change of these parameters respectively (a and c) between $x = 0$ and $x = 15\%$ of zirconium, calculated by equation (1) is $3.86 \cdot 10^{-1}$ $8.41 \cdot 10^{-3}$.

$$\text{Rate of change} = (\Delta g/g) * 100 = (g_2 - g_1 / g_2) * 100 \quad (1)$$

or

g_1 : The lattice parameter value for $x = 0$

g_2 : The lattice parameter value for $x = 0$

As regards the evolution of the lattice parameter (a) of the BTZx powder with x up to 15% , the same trend was observed by Jong-Yoon Ha et al (Ha et al., 2007) in the case of $(\text{Ba}_{0.6}\text{Sr}_{0.4})(\text{Ti}_{1-x}\text{Zr}_x)\text{O}_3$ ($0.05 \leq x \leq 0.3$). On the other hand it is observed that the higher the zirconium rate increases over the tetragonality of phase decreases and is accompanied by the approximation of the lattice parameters a and c , and especially from 7.5% . This Will Lead to Reduced internal stress due to the formation of 90 deg ferroelectric domains. Calculating the volume from the cell parameters (Table 1), shows an increase of cell volume with the increase in the zirconium fraction (from 64.719 to 65.227 \AA^3). Referring to the Vegard's law (Fournet, G., 1953) which states that in solid substitution solutions, the network parameter varies with the atomic composition, it suggests that the formed main phase would probably be a solid solution in which zirconium atoms occupy certain positions in the titanium crystal lattice of BaTiO_3 . This increase in volume is due to the size effect of the substituent atom. Indeed the ionic radius of zirconium (0.74 \AA) being greater than that of titanium

(0.61 \AA). This results in a slight distortion of the mesh. This type of variation is typical to that observed by some authors in $\text{CaTi}_{1-2x}\text{Fe}_x\text{Nb}_x\text{O}_3$ compounds (Koopmans et al., 1983). The Raman spectrum in dependence of the composition of solid-

solution $\text{BaTi}_{1-x}\text{Zr}_x\text{O}_3$, is shown in Fig .3 for a wide range of frequency $100\text{-}1000 \text{ cm}^{-1}$ and carried out at room temperature. On the Raman spectrum of pure barium titanate, we observe

certain active modes of phonons. Indeed, there is the existence of a narrow band 305cm^{-1} associated with modes B_1 and $E(\text{TO}_3+\text{LO}_2)$ which are attributed to the tetragonal phase and a broad and asymmetric band at 520cm^{-1} associated with modes $A_1(\text{TO}_3)$ and $E(\text{TO}_4)$. Finally, it is another broad band (low intensity) to 720cm^{-1} associated with A_1 modes (LO_3) and $E(\text{LO}_4)$ characteristic of the presence of quadratic BaTiO_3 phase, which is in agreement with the results of X-ray. On the other hand we note the presence of three small peaks located respectively at 200cm^{-1} , 230cm^{-1} and 285cm^{-1} associated with modes $A_1(\text{TO}_1)$, $A_1(\text{LO}_1)$ and $A_1(\text{TO}_2)$, which are part of Raman spectrum pure BT. For the doped barium titanate to 2.5% zirconium (Fig. 3), it is noted that the two peaks at 230 and 285cm^{-1} in the barium titanate (BaTiO_3), are transformed into a single broad band between 210 and 290cm^{-1} and $\text{BTZ}_{2.5}$ mode $A_1(\text{TO})$ moves to lower frequencies. However, the increase rate of the zirconium causes the total distribution of these three modes in one broader fashion and significant decrease in the intensity of the latter. This is a clear indication that the addition of zirconium causes the disorder in the BaTiO_3 structure. On the other hand there is much the decrease in intensity of E manual ($\text{TO}_3 + \text{LO}_2$) / B_1 and the widening of the band $E(\text{LO}_4)/A_1(\text{LO}_3)$.

Fig. 3. Raman spectra for BTzX powders for different Zr concentration calcined at 900 °C for 4h

These are the consequence of the presence of different types of cations and anions, namely Ba^{2+} , Zr^{4+} , Ti^{4+} , O^{2-} , and confirmed well the disordered nature of the phase, indicating that the phase is pseudo-cubic. These results are consistent with those found on the barium titanate doped lanthanum (Liu, Y., 2009). It is possible that, in the case of pure BaTiO_3 , BaO and TiO bonds characteristic of the tetragonal structure oscillate with different frequencies and, therefore, they display two different absorption bands $A_1(\text{TO})$, $A_1(\text{LO})$. The addition of the dopant appears to couple these two links, this resulting in the appearance of a single wide band which, in our case, is between 190 and 290cm^{-1} .

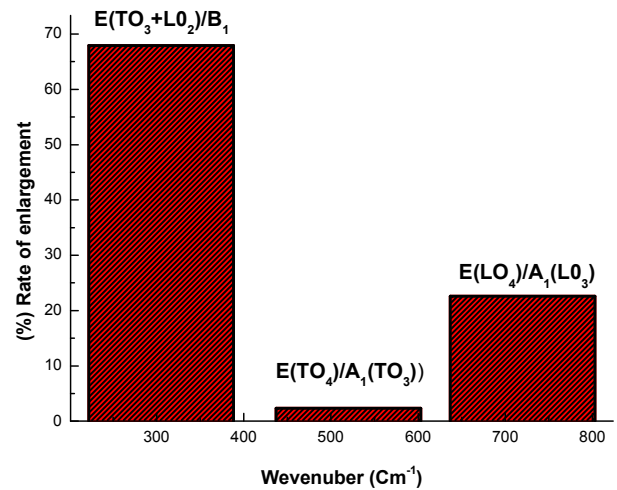

Fig. 4. The enlargement rate of the modes $E(\text{LO}_4) / A_1(\text{LO}_3)$, $E(\text{TO}_3 + \text{LO}_2) / B_1$ and $E(\text{TO}_4) / A_1(\text{TO}_3)$ of BTzX

To better exploit the Raman spectra of BTzX, we have adjusted to determine the settings for each mode are: mid-height width FWHM (full width at half maximum) and the center (frequency). On the results after the adjustment by cushioning response of an oscillator function that satisfies the Boltzmann statistics ($\sim 1-\exp(-x)/KT$), the results obtained (tableau. II) shows the positions of E modes (TO_3+LO_2)/ B_1 and

$E(\text{LO}_4)/A_1(\text{LO}_3)$ move toward the high frequencies with increasing zirconium rates against the E mode $(\text{TO}_3 + \text{LO}_2)/B_1$ moves toward the low frequencies that which is in agreement with the effect of strontium on the BaTiO_3 vibration modes (Kuo et al., 2001, Zhang et al., 2009 and Xia et al., 2012). However the change of peak positions (tableau.II) is accompanied by an increase in the FWHM for all studied modes (tableau.II) which confirms the incorporation and zirconium effect on the barium titanate structure. However it is of interest to note that the rate of enlargement mode E $(\text{LO}_4) / A_1 (\text{LO}_3)$ and E $(\text{TO}_3+\text{LO}_2)/B_1$ is very important 22.07% and 67.91%, respectively (Fig. 4) which shows the gradual distortion of quadratic mesh and its evolution to the pseudo-cubic phase. This is in good agreement with several studies (Frey et al., 1996; Suzuki et al., 2006 and Cho et al., 1998). This work shows that these two bands are specific modes to the tetragonal phase of BaTiO_3 as they disappear above the Curie temperature (T_c) when the structure is cubic. In addition the small of enlargement (2.32%) mode $E(\text{TO}_4)/A_1(\text{TO}_3)$ (Fig. 4) may be connected to the relative increase in lattice parameter c.

Conclusion

The structural analysis results found by XRD and Raman spectroscopy showed that the effect of doping with zirconium, is to change the structure of the tetragonal phase to the pseudo cubic phase by the large increase in lattice parameter a. Therefore, increasing Zr promotes the increase of the symmetry. The adjustment of Raman spectra, helps provide additional information about the center and mid-height width FWHM of each peak. The doping of BaTiO_3 by 15% zirconium causes significant broadening of the modes E $(\text{LO}_4) / A_1 (\text{LO}_3)$ (above 25%) and E $(\text{TO}_3 + \text{LO}_2) / B_1$ (above 50%) characteristic of the tetragonal phase BaTiO_3 .
